January 29, 2017

1   Introduction

To understand different antenna characteristics this laboratory work focused on working with a spectrum analyser and different antennas. After a theoretical part introducing antenna parameters, the practical work was divided in three different setups.

First, a general understanding of a spectrum analyser is gained by testing different functions and using demodulation techniques on different signals. The second part puts the emphasis on the transmission line between a transmitting and receiving antenna and last part shows antenna radiation patterns and their dependence on distance and angle.

2   Theoretical part

Assuming general EM-wave propagation is well known and understood, this theoretical part focuses on the most important antenna features and parameters for this specific laboratory work.
2.1   Modulation

In general, modulation

Figure 1: AM and FM modulation of a Signal onto a Carrier [1]

2.2   Antenna Gain and Impedance

Antenna Gain is closely related to the antenna's directivity, means it corresponds to how concentrated the radiated power is in one specific direction. Gain, however, is the product of the

---

[1]Source: http://www.hill2dot0.com

antennas efficiency and the directivity, and is usually measured in direction of the highest To maximise the radiated power by an antenna, it is important to "match" the impedance of the antenna to the electric circuit, since antennas are resonant devices, e.g. a part of the input power at the antenna will be reflected, which can introduce a whole range of problems, especially when high power is transmitted/reflected back to the transmitter. This reflected power can be minimised by so-called impedance matching, where the impedance of an antenna relates the voltage and current at the input of the antenna.

2.3   VSWR

As stated in the last section, not all of the input power is radiated by the antenna, but is partially reflected. The mismatch of a load Z_L to a source Z_S can be expressed with the so-called *reflection coefficient*:

$$R = \frac{Z_L - Z_S}{Z_L + Z_S} = \frac{V_{incident}}{V_{reflected}} \tag{1}$$

Using this reflection coefficient, the *Voltage Standing Wave Ratio* can be calculated. The VSWR is a common term to express how efficient the power is transmitted from the power source into the load. In physical terms, the VSWR measures the ratio between the highest and lowest voltage (basically the voltage variance) across the transmission line. If there is no reflected power, e.g. all of the power is transmitted, then no interference of the original signal and the reflected occurs. This results in a VSWR of 1. However, if there is some power reflected this will cause constructive and destructive interference with the input signal, which will result in a $VSWR \geq 1$. It is important to note that the VSWR is depending and varying with the frequency, since the impedance will change with increased or decreased frequency. In practical terms, the VSWR can be calculated as

$$VSWR = \frac{1 + |R|}{1 - |R|} \tag{2}$$

The Power Loss due to this reflection can then be calculated using the VSWR:

$$L_{return} = 20 \log_{10} \frac{VSWR - 1}{VSWR + 1} \tag{3}$$

To express this loss in terms of percentage of the input power, one can use so-called *conversion tables* (see appendix), which allows to match a specific VSWR value to the Losses in Percent, or one can calculate it using the reflection coefficient and the following formula:

$$P_{reflected}(\%) = 100 * R^2 \tag{4}$$

2.4   Transmitted Power

After having introduced the VSWR and thus the true emitted & reflected power, we now want to characterise and take a brief look at the power received at the receiver. In general, the Power received is governed by the following equation

$$P_r(dB) = P_e - L_C + G_1 + G_2 - L_P \tag{5}$$

with P_e being the emitted power in dB, L_C the losses of a cable, if there is one in-between the antenna and the power source and G_1 and G_2 the Gain of receiving respectively emitting antenna. L_P is the Path Loss, means the power that is lost due to transmission of power in the air. The Path Loss is dependant on the distance of receiver and emitter, but also on the frequency of the used signal. It can be calculated as follows:

$$L_P = 22 + 20\log(d \times \lambda^{-1}) \tag{6}$$

3   Experiments

3.1   Radio antenna & Spectrum Analyser

To perform all the experiments, we were provided a DSA800 Series Spectrum Analyser manufactured by RIGOL Technologies with a frequency range from 9 kHz to 1.5 Ghz and a resolution of 1Hz. To familiarise oneself with the Spectrum Analyser, we used a simple Dipole Antenna and connected it to the Input of the Spectrum Analyser (SA). Using the full span of the SA we observed different peaks at different frequencies, shown on the screen of the SA - where the X-axis denotes the signal power in dB and the Y-axis the frequency (range). In general, the lowest observable power was about -60dB, which we considered as being the background noise. By selecting the frequency range with upper and lower limits such as we were within the radio frequency band (between 85 and 110 MHz), we were able to see again peaks at different frequencies. After choosing one of the higher peaks and setting its corresponding frequency as center frequency, we used the Demodulation-function of the SA to demodulate the signal, which we expected to be frequency-modulated since this is the common modulation for conventional radio signals. By connecting a set of speakers to the audio output of the SA, we were able to hear the demodulated FM signal in the audible frequency spectrum.

By modifying and testing different resolution times we were able to increase the quality and steadiness of the audible signal. We performed the described procedure with multiple detected peaks in the radio band to test the reception of different modulated signals.

3.2   VSWR measurement

To characterise three different dipole antennas and their efficiency, we measured the Voltage Standing Wave Ratio (VSWR). The SA itself can not measure the VSWR, but by connecting a VSWR-bridge, which essentially feeds the reflected power back to one of the SA's input, this measurement is made possible.

By setting the SA to the *VSWR-measurement*-mode, where the SA automatically detects the connected VSWR device and creating a signal with the SA's build-in Signal Generator, the general setup for this measurement was done. The VSWR-bridge then had to be calibrated by using the calibration function of the SA (**MEA**-¿**Measure Setup**-¿**Calibration Open**). The calibration essentially measures the internal impedances, so that after connecting an antenna the internal impedances will not show up in the measurement.

	Antenna 1	Antenna 2	Antenna 3
Frequency	433 MHz	840 MHz	840 MHz
Peak	457.5 MHz	847.5 MHz	836.5 MHz
3dB BW	42.5 MHz	90.0 MHz	102.5 MHz
Reflected Power	2.5 %	2.21 %	6.43 %
Return Loss	16.0 dB	16.9 dB	12.6 dB
VSWR	1.38	1.35	1.68

Table 1: Antenna characteristics for three omnidirectional antennas

Comparing the Reflected Power of the three respective antennas we can see that all antennas are below 10%, the threshold for an antenna being seen as having a good performance in terms of transmitting power.

3.3   Antenna Gain

Having measured the Reflected Power for the three provided antennas, we now want to calculate the Gain of the antennas. This is done using a calibrated broadband antenna which has a Gain of 2.9 dBi as a transmitting antenna. The setup here is similar to the setup of the VSWR measurement, but now we do not use the VSWR bridge. Instead, we connect the transmitting antenna directly to the SA TX output and the receiving antenna via a short cable to the SA RX input. Now we set the transmitting frequency to the calibrated antenna's peak frequency of 840MHz and the SA's emitting power to 0 dB. Placing the receiving antenna at a distance equal to the wavelength ($\lambda = d = 35.714cm$) and measure the received power at the uncalibrated receiving antenna, we can now calculate the Gain of the receiving antenna with eq. (5) given in section 2.4.

	Antenna 2	Antenna 3
received Power (dBm)	-24.0	-26.3
calculated Gain (dBi)	-4.4	-6.7

Table 2: received Power and Gain at receiver antenna

Since the used calibrated broadband antenna did not support frequencies as low as 433 MHz, only the gain of two of the three antennas could be characterised using this method. As for the losses in the cable we used a value of 0.5dBm, a value that was provided by the instructions.

The calculated Gain and the received power fit our VSWR measurements very well. One can easily see that Antenna 3 has a lower Gain value, which corresponds to our previous observation that Antenna 3 has higher return losses, c.f. table 1.

3.4   Received Power vs. Distance

To show the dependency of received power strength and distance between emitter and receiver, we used a small wireless remote, as is usually used for garage door opener. Since this device operates at around 433 MHz, we hooked Antenna 1 onto the Spectrum Analyser. Starting with a distance of $d = \lambda = 0.693m$ in-between the transmitter device and the receiving antenna, we increased the distance in steps of $20cm$ each, and measured the power received at the Spectrum Analyser. The received power plotted vs. the distance can be seen in fig. 2 An observation

Figure 2: Received Power vs. Distance

we made, is that the received power fluctuates quite a lot. We expected the power to decrease more or less linearly, but the measured data looks very scattered. However, using a least-square

linear approximation to the measured data, shows a definite trend towards decreasing power with increased distance. The fluctuating power might be explained by having obstacles, e.g. multi-path effects, since the room we performed all the experiments, was not shielded. Also we noticed high variations in the measured power, depending where in the room we were standing - even when not standing in line-of-sight between transmitter and receiver. Another reason might be, that the distance measurement was not as precise as we would have wished, since we used an ordinary table and a tape measure to measure the distance from receiving antenna to the transmitter.

3.5   Antenna Gain Pattern

The final experiment in this laboratory was the measurement of a high-precision high-gain antenna, the Hyperlog 7025.
